# Differential expression with RNA-seq: Technical Details 

Lieven Clement

Transcriptomics

## Exponential family

$$
f\left(y_{i} \mid \theta_{i}, \phi\right)=\exp \left\{\frac{y_{i} \theta_{i}-b\left(\theta_{i}\right)}{a(\phi)}+c\left(y_{i}, \phi\right)\right\}
$$

with

- $\theta_{i}$ : canonical parameters
- $\phi$ : dispersion parameter
- $a(),. b(),. c():$. specific functions that depend on the distribution, e.g. for normal distribution $\phi=\sigma^{2}, \theta=\mu$, $a(\phi)=\phi=\sigma^{2}, b\left(\theta_{i}\right)=\theta_{i}^{2} / 2, c\left(y_{i}, \phi\right)=-\frac{1}{2}\left[y^{2} / \phi+\log (2 \pi \phi)\right]$

## Components of Generalized Linear Model

$$
\left\{\begin{aligned}
y_{i} \mid x_{i} & \sim f\left(y_{i} \mid \theta_{i}, \phi\right) \\
\mathrm{E}\left[y_{i} \mid \mathbf{x}_{i}\right] & =\mu_{i} \\
g\left(\mu_{i}\right) & =\eta\left(\mathbf{x}_{i}\right) \\
\eta\left(\mathbf{x}_{i}\right) & =\mathbf{x}_{i}^{T} \boldsymbol{\beta}
\end{aligned}\right.
$$

with $g($.$) the link function, e.g.$

- $g()=$.. : identity link for Normal distribution
- $g()=.\log ($.$) : canonical link for Poisson distribution$
- $g()=.\operatorname{logit}()=.\log \left[\frac{(.)}{(1-.)}\right]$ : canonical link for Bernouilli distribution.

## Parameter estimation: the likelihood

- We start from a sample, and consider it as fixed and known.
- In particular we do NOT consider the sample observations as random variables.
- Therefore we write the observed sample as $y_{i}, \ldots, y_{n}$
- The theory is based on the likelihood function, which can be interpreted as a measure for the probability that the given sample is observed as a realisation of a sequence of random variables $Y_{1}, \ldots Y_{n}$.
- The random variables $Y_{i}$ are characterised by a distribution or density function which has typically unknown parameters, e.g. a Poisson distribution $f\left(Y_{i}\right) \sim \operatorname{Poisson}\left(\theta_{i}\right)$.

## Parameter estimation: the likelihood

- When the subjects are mutually independent the joint likelihood to observe $y_{1}, \ldots, y_{n}$ equals

$$
\prod_{i=1}^{n} f\left(y_{i}, \theta_{i}, \phi\right)
$$

- The densities are actually also a function of the parameters $\theta_{i}, \phi$. To stress this, we indicated that in the density formulation.
- The likelihood function is a function of all parameters

$$
L(\boldsymbol{\theta}, \phi \mid \mathbf{y})=\prod_{i=1}^{n} f\left(y_{i}, \theta_{i}, \phi\right)
$$

- The log-likelihood function is often used, which is defined as

$$
I(\boldsymbol{\theta}, \phi \mid \mathbf{y})=\log L(\boldsymbol{\theta}, \phi \mid \mathbf{y})=\sum_{i=1}^{n} \log f\left(y_{i}, \theta_{i}, \phi\right)
$$

## log-likelihood

$$
I\left(\theta_{i}, \phi \mid y_{i}\right)=\left\{\frac{y_{i} \theta_{i}-b\left(\theta_{i}\right)}{a(\phi)}+c\left(y_{i}, \phi\right)\right\}
$$

- $E\left[y_{i}\right]=\mu_{i}=b^{\prime}\left(\theta_{i}\right)$
- $\operatorname{var}\left[y_{i}\right]=b^{\prime \prime}\left(\theta_{i}\right) a(\phi)$

Variance $\operatorname{var}\left[y_{i}\right]$ depends on mean! Often there is no dispersion parameter e.g. Bernouilli: var $\left[y_{i}\right]=\mu_{i}\left(1-\mu_{i}\right)$, Poisson $\operatorname{var}\left[y_{i}\right]=\mu_{i}$.

## Maximum likelihood, Score function

$$
S_{i}\left(\theta_{i}\right)=\frac{\partial I\left(\theta_{i}, \phi \mid y_{i}\right)}{\partial \theta_{i}}
$$

when canonical link function is used:

- $\mu_{i}=b^{\prime}\left(\theta_{i}\right)$

## Maximum likelihood, Score function

$$
S_{i}\left(\theta_{i}\right)=\frac{\partial I\left(\theta_{i}, \phi \mid y_{i}\right)}{\partial \theta_{i}}=\frac{y_{i}-\mu_{i}}{a(\phi)}
$$

when canonical link function is used:

- $\mu_{i}=b^{\prime}\left(\theta_{i}\right)$

## Maximum likelihood, Score function

$$
S_{i}\left(\theta_{i}\right)=\frac{\partial I\left(\theta_{i}, \phi \mid y_{i}\right)}{\partial \theta_{i}}=\frac{y_{i}-\mu_{i}}{a(\phi)}
$$

when canonical link function is used:

- $\mu_{i}=b^{\prime}\left(\theta_{i}\right)$
- Regression (chain rule and $i=1, \ldots, n$ i.i.d observations)

$$
\begin{gathered}
S_{i}(\boldsymbol{\beta})=\frac{\partial I\left(\theta_{i}, \phi \mid ; y_{i}\right)}{\partial \theta_{i}} \frac{\partial \theta_{i}}{\partial \mu_{i}} \frac{\partial \mu_{i}}{\partial \eta_{i}} \frac{\partial \eta_{i}}{\partial \boldsymbol{\beta}}=\mathbf{x}_{i} S_{i}\left(\theta_{i}\right) \frac{1}{b^{\prime \prime}\left(\theta_{i}\right)} \frac{\partial \mu_{i}}{\partial \eta_{i}} \\
S(\boldsymbol{\beta})=\sum_{i=1}^{n} \mathbf{x}_{i} \frac{y_{i}-\mu_{i}}{a(\phi) b^{\prime \prime}\left(\theta_{i}\right)} \frac{\partial \mu_{i}}{\partial \eta_{i}}=\mathbf{X}^{T} \mathbf{A}(\mathbf{y}-\boldsymbol{\mu})
\end{gathered}
$$

- $\mathbf{A}$ is a diagonal matrix: $\mathbf{A}=\operatorname{diag}\left[\operatorname{var}\left[y_{i}\right] \frac{\partial \eta_{i}}{\partial \mu_{i}}\right]^{-1}$,

$$
\mathbf{y}=\left[y_{1}, \ldots, y_{n}\right]^{T}, \boldsymbol{\mu}=\left[\mu_{1}, \ldots, \mu_{n}\right]^{T}
$$

- Optimization??

## Newton Raphson

$$
\begin{aligned}
& \qquad \hat{\boldsymbol{\beta}}: S(\boldsymbol{\beta})=0 \\
& \boldsymbol{\beta}^{k+1}=\boldsymbol{\beta}^{k}-\left(\left.\frac{\partial S(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}}\right|_{\boldsymbol{\beta}^{k}}\right)^{-1} S\left(\boldsymbol{\beta}^{k}\right) \\
& \boldsymbol{\beta}^{k+1}=\boldsymbol{\beta}^{k}+\left.J^{-1}\left(\boldsymbol{\beta}^{k}\right)\right|_{\boldsymbol{\beta}^{k}} S\left(\boldsymbol{\beta}^{k}\right) \\
& \text { with } J\left(\boldsymbol{\beta}^{k}\right) \text { the observed Fisher } \\
& \text { information matrix. }
\end{aligned}
$$

- Fisher scoring: replace observed Fisher information matrix $J\left(\boldsymbol{\beta}^{k}\right)$ by expected Fisher information matrix $I\left(\boldsymbol{\beta}^{k}\right)=\mathrm{E}\left[J\left(\boldsymbol{\beta}^{k}\right)\right]$.
- If you use canonical link, $I\left(\boldsymbol{\beta}^{k}\right)=J\left(\boldsymbol{\beta}^{k}\right) \rightarrow$ Fisher Scoring and Newton Raphson are identical.

## Iteratively Reweighted Least Squares (IRLS)

Newton Raphson and Fisher Scoring can be recasted in an IRLS algorithm

$$
\begin{aligned}
\boldsymbol{\beta}^{k+1} & =\boldsymbol{\beta}^{k}+\left.I^{-1}\left(\boldsymbol{\beta}^{k}\right)\right|_{\boldsymbol{\beta}^{k}} S\left(\boldsymbol{\beta}^{k}\right) \\
& =\boldsymbol{\beta}^{k}+\left(\mathbf{X}^{T} \mathbf{W} \mathbf{X}\right)^{-1} \mathbf{X}^{T} \mathbf{A}(\mathbf{y}-\boldsymbol{\mu}) \\
& =\boldsymbol{\beta}^{k}+\left(\mathbf{X}^{T} \mathbf{W} \mathbf{X}\right)^{-1} \mathbf{X}^{T} \mathbf{W} \frac{\partial \eta}{\partial \mu}(\mathbf{y}-\boldsymbol{\mu}) \\
& =\left(\mathbf{X}^{T} \mathbf{W} \mathbf{X}\right)^{-1} \mathbf{X}^{T} \mathbf{W}\left[\mathbf{X} \boldsymbol{\beta}^{k}+\frac{\partial \eta}{\partial \mu}(\mathbf{y}-\boldsymbol{\mu})\right] \\
& =\left(\mathbf{X}^{T} \mathbf{W} \mathbf{X}\right)^{-1} \mathbf{X}^{T} \mathbf{W} \mathbf{z}
\end{aligned}
$$

with $I(\boldsymbol{\beta})=\mathbf{X}^{T} \mathbf{W} \mathbf{X}, \mathbf{W}=\mathbf{A d i a g}\left[\frac{\partial \eta}{\partial \mu}\right]^{-1}$ and pseudo data $\mathbf{z}=\boldsymbol{\eta}+\frac{\partial \boldsymbol{\eta}}{\partial \boldsymbol{\mu}}(\mathbf{y}-\boldsymbol{\mu})$

# Differential expression analysis of multifactor RNA-Seq experiments with respect to biological variation

## ABSTRACT

A flexible statistical framework is developed for the analysis of read counts from RNA-Seq gene expression studies. It provides the ability to analyse complex experiments involving multiple treatment conditions and blocking variables while still taking full account of biological variation. Biological vari ation between RNA samples is estimated separ ately from the technical variation associated with sequencing technologies. Novel empirical Bayes methods allow each gene to have its own specific variability, even when there are relatively few bio logical replicates from which to estimate such variability. The pipeline is implemented in the edgeR package of the Bioconductor project. A case study analysis of carcinoma data demonstrates the ability of generalized linear model methods (GLMs) to detect differential expression in a paired design and even to detect tumour-specific expression changes. The case study demonstrates the need to allow for gene-specific variability, rather than assuming a common dispersion across genes or a fixed relationship between abundance and vari ability. Genewise dispersions de-prioritize genes with inconsistent results and allow the main analysis to focus on changes that are consisten between biological replicates. Parallel computation al approaches are developed to make non-linea model fitting faster and more reliable, making the application of GLMs to genomic data more convenient and practical. Simulations demonstrate the ability of adjusted profile likelinood estimators to return accurate estimators of biological variability
in complex situations. When variation is genespecific, empirical Bayes estimators provide an advantageous compromise between the extremes of assuming common dispersion or separate genewise dispersion. The methods developed here can also be applied to count data arising from DNA-Seq applications, including ChIP-Seq for epigenetic marks and DNA methylation analyses.

## INTRODUCTION

The cost of DNA sequencing continues to decrease at a staggering rate (1). As it does, sequencing technologies become more and more attractive as platforms for studying gene expression. Current 'next-generation' sequencing technologies measure gene expression by generating short reads or sequence tags, that is, sequences of $35-300$ base pairs that correspond to fragments of the original RNA. There are a number of technologies and many different protocols. Popular approaches are either tag-based methods including Tag-Seq (2), deepSAGE (3), AGE-Seq (4), which sequence from one or more anchored positions in each gene, or RNA-Seq ( $\mathrm{S}-8$ ), scriptome. Both approaches have proven successful in mestigating gene expression and regulation (9-11) In this article, we will use the term RNA-Seq generically o include any of the tag-based or RNA-Seq variants in which very high-throughput sequencing is applied to RNA ragments.
For the purposes of evaluating differential expression between conditions, read counts are summarized at the genomic level of interest, such as genes or exons. Although RNA-Seq can be used to search for novel exons or for splice-variants and isoform-specific

## MATERIALS AND METHODS

## Biological coefficient of variation

RNA-Seq profiles are formed from $n$ RNA samples. Le $\pi_{R i}$ be the fraction of all cDNA fragments in the $i$-th sample that originate from gene $g$. Let $G$ denote the total number of genes, so $\sum_{\delta=1}^{G} \pi_{x i}=1$ for each sample. Let $\sqrt{\phi_{\mathrm{g}}}$ denote the coefficient of variation (CV) (standard deviation divided by mean) of $\pi_{g i}$ between the replicates $i$. We denote the total number of mapped read at map to the $g$-th gene by $y_{k j}$. Then

$$
E\left(y_{g i}\right)=\mu_{g i}=N \mid \pi_{g l-}
$$

Assuming that the count $y_{g i}$ follows a Poisson distribution for repeated sequencing runs of the same RNA sample, a well known formula for the variance of a mixture distri bution implies
$\operatorname{var}\left(y_{g i}\right)=E_{\pi}[\operatorname{var}(y \mid \pi)]+\operatorname{var}_{s}[E(y \mid \pi)]=\mu_{g i}+\phi_{g} \mu_{g i}^{2}$.
Dividing both sides by $\mu_{g i}^{2}$ gives

$$
\mathrm{CV}^{2}\left(y_{k j}\right)=1 / \mu_{g t}+\phi_{g}
$$

The first term $1 / \mu_{g i}$ is the squared CV for the Poisson distribution and the second is the squared CV of the unobserved expression values. The total $\mathrm{CV}^{2}$ therefore is the technical $\mathrm{CV}^{2}$ with which $\pi_{8 i}$ is measured plus the biological $\mathrm{CV}^{2}$ of the true $\pi_{\mathrm{g} \text {. }}$. In this article, we call $\phi_{\mathrm{g}}$ the dispersion and $\sqrt{\phi_{k}}$ the biological CV although, strictly speaking, it captures all sources of the inter-library variation between replicates, including perhaps contributions from technical causes such as library preparation as wel as true biological variation between samples.

GLMs
GLMs are an extension of classical linear models to non-normally distributed response data $(42,43)$. GLMs specify probability distributions according to their mean-variance relationship, for example the quadratic mean-variance relationship specified above for read counts. Assuming that an estimate is available for $\phi_{8}$, so the variance can be evaluated for any value of $\mu_{8}$ GLM theory can be used to fit a log-linear model

$$
\log \mu_{g I}=\mathbf{x}_{i}^{T} \beta_{g}+\log N_{i}
$$

for each gene $(32,41)$. Here $\mathbf{x}_{i}$ is a vector of covariates that specifies the treatment conditions applied to RNA sample $i$, and $\beta_{z}$ is a vector of regression coefficients by which the covariate effects are mediated for gene $g$. Th GLM distributional farnily. The use of the negative binomial distribution is equivalent to treating the ention is equivalent to treating the $\pi_{p i}$ as gamma distributed.

## Fitting the GLMs

The derivative of the log-likelihood with respect to the coefficients $\beta_{g}$ is $X^{T} \mathbf{z}_{g}$, where $X$ is the design matrix with columns $\mathbf{x}_{i}$ and $z_{g i}=\left(y_{g i}-\mu_{g}\right) /\left(1+\phi_{g} \mu_{g}\right)$. The Fisher
information matrix for the coefficients can be written as $I_{g}=X^{J} W_{g} X$, where $W_{g}$ is the diagonal matrix of working weights from standard GLM theory (43). The Fisher coring iteration to find the maximum likelihood estimate of $\beta_{g}$ is therefore $\beta_{g}^{\text {oww }}=\beta_{g}^{\text {old }}+\delta$ with $\delta=\left(X^{T} W_{g} X\right)^{-1} X^{T} \mathbf{Z}_{g}$. This iteration usually produces an increase in the likelihood function, but the likelihood can also decrease representing divergence from the required solution. On the other hand, there always exists a stepsize modifier $\alpha$ with $0<\alpha<1$ such that $\beta_{8}^{\text {new }}=\beta_{g}^{\text {odd }}+\alpha \delta$ produces an increase in the likelihood. Choosing $\alpha$ so that this is so at each iteration is known Fisher's scoring iteration can
Fisher's scoring iteration can be viewed as an approximate Newton-Raphson algorithm, with the Fisher informatrix. The line search strategy may be used with any pproximation to the second derivative matrix that is positive definite. Our implemention uses a computationally convenient approximation. Without loss of generality, the convenient approximation. Without loss of generality, the
linear model can be parametrized so that $X^{T} X=I$. If this is done, and if the $\mu_{2 i}$ also happen to be constant over $i$ for a given gene $g$, then the information matrix simpifies considerably to $\mu_{g}\left(1+\phi_{g} \mu_{g}\right)$ times the identity matrix $I$. Taking this as the approximation to the information matrix, the Fisher scoring step with line search modification becomes simply $\delta=\alpha X^{T} \mathbf{z}_{g}$, where the multiplier $\mu_{g} /\left(1+\phi_{R} \mu_{g}\right)$ has been absorbed into the stepsize factor $\alpha$. In this formulaion, $\alpha$ is no longer constrained to be less than one. In our mplementation, each gene has its own stepsize $\alpha$ that is increased or decreased as the iteration proceeds.

## Cox-Reid adjusted profile likelihood

The adjusted profile likelihood (APL) for $\phi_{g}$ is the penalized log-likelihood

$$
\mathrm{APL}_{g}\left(\phi_{g}\right)=\ell\left(\phi_{g} ; \mathbf{y}_{g}, \hat{\beta}_{g}\right)-\frac{1}{2} \log \operatorname{det} \mathcal{I}_{g} .
$$

where $y_{g}$ is the vector of counts for gene $g, \beta_{g}$ is the estimated coefficient vector, $\ell 0$ is the log-likelihood unction and $I_{g}$ is the Fisher information matrix. The Cholesky decomposition (46) provides a numerically table and efficient algorithm for computing the determinnt of the information matrix. Specifically, logdet $\mathcal{I}_{g}$ is the sum of the logarithms of the diagonal elements of the Cholesky factor $R$, where $\mathcal{I}_{g}=R^{T} R$ and $R$ is upper tringular. The matrix $R$ can be obtained as a by product of he QR-decomposition used in standard linear model fitting. In our implementation, the Cholesky calculations are carried out in a vectorized fashion, computed for all genes in parallel.

## Simulations

Artificial data sets were generated with negative binomial distributed counts for a fixed total number of 10000 genes. The expected count size varied between genes according to a gamma distribution with shape parameter 0.5 , an ad hoc choice that happened to mimic the size distribution of the carcinoma data. The average dispersion was set to 0.16 $\mathrm{BCV}=0.4)$. In one simulation, all genes had the same

## Defining model

## MATERIALS AND METHODS

Biological coefficient of variation
RNA-Seq profiles are formed from $n$ RNA samples. Le $\pi_{R i}$ be the fraction of all cDNA fragments in the $i$-th sample that originate from gene $g$. Let $G$ denote the total number of genes, so $\sum_{\delta=1}^{G} \pi_{x i}=1$ for each sample. Let $\sqrt{\phi_{\text {g }}}$ denote the coefficient of variation (CV) (standard deviation divided by mean) of $\pi_{g i}$ between the replicates $i$. We denote the total number of mapped read
 by $y_{k j}$. Then

$$
E\left(y_{g g}\right)=\mu_{g i}=N i \pi_{g l-}
$$

Assuming that the count $y_{g i}$ follows a Poisson distribution for repeated sequencing runs of the same RNA sample, a well known formula for the variance of a mixture distri bution implies
$\operatorname{var}\left(y_{g}\right)=E_{\pi}[\operatorname{var}(y \mid \pi)]+\operatorname{var}_{s}[E(y \mid \pi)]=\mu_{g i}+\phi_{g} \mu_{g i}^{2}$.
Dividing both sides by $\mu_{g i}^{2}$ gives

$$
\mathrm{CV}^{2}\left(y_{k}\right)=1 / \mu_{g_{t}}+\phi_{g} .
$$

The first term $1 / \mu_{g i}$ is the squared CV for the Poisson distribution and the second is the squared CV of the unobserved expression values. The total $\mathrm{CV}^{2}$ therefore is the technical $\mathrm{CV}^{2}$ with which $\pi_{r i}$ is measured plus the biological $\mathrm{CV}^{2}$ of the true $\pi_{\mathrm{g} \text {. }}$. In this article, we call $\phi_{\mathrm{g}}$ the dispersion and $\sqrt{\phi_{,}}$the biological CV although, strictly speaking, it captures all sources of the inter-library variation between replicates, including perhaps contributions from technical causes such as library preparation as wel as true biological variation between samples.

GLMs
GLMs are an extension of classical linear models to non-normally distributed response data $(42,43)$. GLMs specify probability distributions according to their mean-variance relationship, for example the quadratic mean-variance relationship specified above for read counts. Assuming that an estimate is available for $\phi_{y}$, so the variance can be evaluated for any value of $\mu_{8}$ GLM theory can be used to fit a log-linear model

$$
\log \mu_{g I}=\mathbf{x}_{i}^{T} \beta_{g}+\log N_{i}
$$

for each gene $(32,41)$. Here $\mathbf{x}_{i}$ is a vector of covariates that specifies the treatment conditions applied to RNA sample $i$, and $\beta_{z}$ is a vector of regression coefficients by which the covariate effects are mediated for gene $g$. The GLM distributional family. The use of the negative binomial distribution is equivalent to treating the $\pi_{\text {a }}$ as ation is equivalent to treating the $\pi_{g i}$ as gamma distributed.

## Fitting the GLMs

The derivative of the log-likelihood with respect to the coefficients $\beta_{g}$ is $X^{T} \mathbf{z}_{g}$, where $X$ is the design matrix with columns $\mathbf{x}_{i}$ and $z_{g i}=\left(y_{k i}-\mu_{g}\right) /\left(1+\phi_{g} \mu_{g}\right)$. The Fishe
information matrix for the coefficients can be written as $I_{g}=X^{T} W_{g} X$, where $W_{q}$ is the diagonal matrix of working weights from standard GLM theory (43). The Fisher coring iteration to find the maximum likelihood estimate of $\beta_{g}$ is therefore $\beta_{g}^{\text {oww }}=\beta_{g}^{\text {old }}+\delta$ with $\delta=\left(X^{T} W_{g} X\right)^{-1} X^{T} \mathbf{Z}_{g}$. This iteration usually produces an increase in the likelihood function, but the likelihood can also decrease representing divergence from the required solution. On the other hand, there always exists a stepsize modifier $\alpha$ with $0<\alpha<1$ such that $\beta_{\mathrm{c}}^{\text {new }}=\beta_{g}^{\text {odd }}+\alpha \delta$ produces an increase in the likelihood. choosing $\alpha$ so that this is so at each iteration is known as a line search strategy $(44,45)$.
Fisher's scoring iteration can be viewed as an approximate Newton-Raphson algorithm, with the Fisher informatrix. The line search strategy may be used with any approximation to the second derivative matrix that is positive definite. Our implemention uses a computationally convenient approximation. Without loss of generality the linear model can be parametrized so that $X^{T} X=I$. If this is done, and if the $\mu_{2 i}$ also happen to be constant over $i$ for a given gene $g$, then the information matrix simpifies considerably to $\mu_{g}\left(1+\phi_{g} \mu_{g}\right)$ times the identity matrix $I$. Taking this as the approximation to the information matrix, the Fisher scoring step with line search modification becomes simply $\delta=\alpha X^{\top} \mathbf{z}_{g}$, where the multipher $\mu_{v}\left(1+\phi_{q} \mu_{p}\right)$ has been absorbed into the stepsize factor $\alpha$. In this formulation, $\alpha$ is no longer constrained to be less than one. In our implementation, each gene has its own stepsize $\alpha$ that is increased or decreased as the iteration proceeds.

## Cox-Reid adjusted profile likelihood

The adjusted profile likelihood (APL) for $\phi_{g}$ is the penalized log-likelihood

$$
\mathrm{APL}_{g}\left(\phi_{g}\right)=\ell\left(\phi_{g} ; \mathbf{y}_{g}, \hat{\beta}_{g}\right)-\frac{1}{2} \log \operatorname{det} \mathcal{I}_{g} .
$$

where $y_{g}$ is the vector of counts for gene $g, \beta_{g}$ is the estimated coefficient vector, $\ell 0$ is the log-likelihood unction and $I_{g}$ is the Fisher information matrix. The Cholesky decomposition (46) provides a numerically table and efficient algorithm for computing the determinant of the information malrix. Specifically, logdet $I_{g}$ is the sum of the logarithms of the diagonal elements of the Cholesky factor $R$, where $\mathcal{I}_{g}=R^{T} R$ and $R$ is upper tringular. The matrix $R$ can be obtained as a by product of he QR-decomposition used in standard linear model fitting. In our implementation, the Cholesky calculations are carried out in a vectorized fashion, computed for all genes in parallel.

## Simulations

Artificial data sets were generated with negative binomial distributed counts for a fixed total number of 10000 genes. The expected count size varied between genes according to a gamma distribution with shape parameter 0.5 , an ad hoc choice that happened to mimic the size distribution of the carcinoma data. The average dispersion was set to 0.16 $\mathrm{BCV}=0.4$ ). In one simulation, all genes had the same

## Defining model

- $b^{\prime \prime}(\theta)=\mu$
- $a(\phi)=1+\phi \mu$

Estimation dispersion: profiling

- $I_{g}=-E\left[\frac{\partial^{2} L}{\partial^{2} \boldsymbol{\beta}}\right]$

Do APL with Gaussian for explaining rationale

$$
\begin{gathered}
-\frac{1}{2} \log \operatorname{det} I=\frac{p}{2} \log \sigma^{2}+\frac{1}{2} \log \left|\mathbf{X}^{T} \mathbf{X}\right| \\
-2 A P L \sim(N-p) \log \sigma^{2}+\frac{1}{\sigma^{2}}\|\mathbf{Y}-\mathbf{X} \boldsymbol{\beta}\|_{2}^{2}
\end{gathered}
$$

Although the pseudo-Newton algorithm requires slightly more iterations on average than true Newton-Raphson or the customary Fisher scoring algorithm for GLMs, the pseudo-Newton algorithm remains competitive in con junction with our line-search strategy, and the computational gains that arise from the simplification are enormous. The algorithm is implemented in R in such a way that the iteration is progressed for all genes in parallel rather than for one gene at a time. Our pure R implementation fits GLMs to most RNA-Seq data sets in a few R typically require minutes at to the gimo function R yypically require mindes al heas, and indeed may fail

## Hypothesis tests

Our software allows users to test the significance of any coefficient in the linear model, or of any contrast or linear combination of the coefficients in the linear model. Genewise lests are conducted by computing likelihoodcoefficient or contrast is equal he zero asinst the two-sided alternative that it is different from zero The log likelihoed etio statistics are asymptotically chi square distributed under the null hypothesis that the co efficient or contrast is zero Simulations show that the likelihood ratio tests hold their size relatively well and generally give a good approximation to the exact tes (23) when the latter is available (data not shown). Any multiple testing adjustment method provided by the p.adjust function in R can be used. By default, $P$-values are adjusted to control the false discovery rate by the method of Benjamini and Hochberg (47).

## Estimation of biological CV

The remaining issue is to obtain a reliable estimate of the BCV for each gene. An estimator that is approximately unbiased and performs well in small samples is required Maximum likelihood estimation of the BCV would underestimate the BCV, because of the need to estimate the Our earlier in the log-linear model from the same data estimate the BCV $(22,23)$. This approach has excellent performance, but does not easily generalize to GLMs Instead we use an approximate conditional likelihood approach known as APL (48). APL is a form of penalized likelihood. Again, we have implemented the APL computation in a vectorized and computationally efficient manner, rather than computing quantities gene by gene.

## Estimating common dispersion

Estimating the BCV for each gene individually should not be considered unless a large number of biological replicates are available. When less replication is available, sharing information between genes is essential for reliable inference. Regardless of the amount of replication, appropriate information sharing methods should result in some benefits.
Let $\phi_{y}$ denote the squared BCV for gene $g$, which we call the dispersion of that gene. The dispersion is the coefficient of the quadratic term in the variance function

The simplest method of sharing information between genes is to assume that all genes share the same dispersion, oo that $\phi_{g}=\phi$ (23). The common dispersion may be estimated by maximizing the shared likelihood function

$$
\operatorname{APL}_{s}(\phi)=\frac{1}{G} \sum_{g=1}^{G} \operatorname{APL}_{g}(\phi) .
$$

where $\mathrm{APL}_{\mathrm{g}}$ is the adjusted profile likelihood for gene $g$ ('Materials and Methods' section). This maximization can be accomplished numerically in a number of ways, for example by a derivative-free approximate Newton algorithm (49)

## Estimating trended dispersion

A generalization of the common dispersion is to model the dispersion $\phi_{g}$ as a smooth function of the average read count of each gene (25). Our software offers a number of methods to do this. A simple non-parametric method is to divide the genes into bins by average read count, estimate the common dispersion in each bin, then to fit loess or spline curve through these bin-wise dispersions. A more sophisticated method is locally weighted APL. In his approach, each $\phi_{g}$ is estimated by making a local shared $\log$-likelihood, which is a weighted average of the APLs for gene $g$ and its neighbouring genes by average read count.

## Estimating genewise dispersions

In real scientific applications, it is more likely that individual genes have individual BCV s depending on their genomic sequence, genomic length, expression level or biological function. We seek a compromise between entirely individual genewise dispersions $\phi_{g}$ and entirely shared values by extending the weighted likelihood empirical In this approach, $\phi_{x}$ is estimated by maximizing

$$
\mathrm{APL}_{g}\left(\phi_{g}\right)+G_{0} \mathrm{APL}_{\mathrm{S}_{8}}\left(\phi_{g}\right),
$$

where $G_{0}$ is the weight given to the shared likelihood and $\mathrm{APL}_{S_{8}}\left(\phi_{g}\right)$ is the local shared log-likelihood. This APL ${ }_{S_{8}}\left(\phi_{g}\right)$ is the local shared log-likelihood. This cal Bayes terms, with the shared likelihood as the prior distribution for $\phi_{p}$ and the weighted likelihood as the posterior. The prior distribution can be thought of as arising from prior observations on a set of $G_{0}$ genes. The number of prior genes $G_{0}$ therefore represents the weight assigned o the prior relative to the actual observed data for gene $g$. The optimal choice for $G_{0}$ depends on the variability of BCV between genes. Large values are best when the BCV is constant between genes. Smaller values are optimal when the BCVs vary considerably between genes. We have found that $G_{0}=20 / \mathrm{df}$ gives good results over a wide range of real data sets, where df is the residual degrees of freedom for estimating the BCV. For multigroup experiments, df is the number of libraries minus the number of distinct treatment groups. The default setting implies that the prior has the weight of 20 degrees of freedom for estimating the BCV, regardless of

$(1-\alpha) A P L_{g}\left(\phi_{g}\right)+\alpha A P L_{S}\left(\phi_{g}\right)$
- DESeq: maximum trended vs tagwise
- DESeq 2: Tagwise but outliers are not shrunken

## Hypothesis testing: Large sample theory

- LRT-test

$$
\lambda=2 I_{e}-2 I_{0}
$$

for nested models (extended model (e) and null model (0)) follows an asymptotic $\chi^{2}$-distribution with $d f=p_{e}-p_{0}$ degrees of freedom and $p_{e}\left(p_{0}\right)$ the number of parameters in the extended (null) model.

- Wald test follows immediately from the information matrix for generalized linear models

$$
I(\beta)=\mathbf{X}^{\top} \mathbf{W} \mathbf{X}
$$

so large sample distribution of the maximum likelihood estimator $\hat{\boldsymbol{\beta}}$ is multivariate normal

$$
\hat{\boldsymbol{\beta}} \sim N\left[\boldsymbol{\beta},\left(\mathbf{X}^{\top} \mathbf{W} \mathbf{X}\right)^{-1}\right]
$$

## Limma-voom

- Count models vs transformation: Poisson counts, $\sqrt{( } y)$ stabilises the variance, insufficient for negative binomial. Log transformation: the transformed data are still heteroscedastic. $\rightarrow$ limma-voom
- Use normalized log-cpm Limma pipeline for sequencing

## Limma-voom

- Problem: counts have a mean variance relationship: heteroscedastic
- How do we deal with heteroscedasticity in traditional linear models?

## Limma-voom

- Problem: counts have a mean variance relationship: heteroscedastic
- How do we deal with heteroscedasticity in traditional linear models?
- Two stage approach:
(1) Stage I
- OLS
- Estimate variances at each data point
- Use variances as weights: $W=\operatorname{diag}\left[1 / \hat{\sigma}_{i}^{2}\right]$
(2) Stage II WLS $\operatorname{argmin}_{\boldsymbol{\beta}}\left\{(\mathbf{y}-\mathbf{X} \boldsymbol{\beta})^{T} \mathbf{W}(\mathbf{y}-\mathbf{X} \boldsymbol{\beta})\right\}$
- Port this idea to RNA-seq pipeline

## Log-counts per million

We assume that an experiment has been conducted to generate a set of $n$ RNA samples. Each RNA sample has been sequenced, and the sequence reads have been summarized by recording the number mapping to each gene. The RNA-seq data consist therefore of a matrix of read counts $r_{g i}$, for RNA samples $i=1$ to $n$, and genes $g=1$ to $G$. Write $R_{i}$ for the total number of mapped reads for sample $i, R_{i}=\sum_{g=1}^{G} r_{g i}$. We define the log-counts per million ( $\log -\mathrm{cpm}$ ) value for each count as

$$
y_{g a}=\log _{2}\left(\frac{r_{g i}+0.5}{R_{i}+1.0} \times 10^{6}\right)
$$

The counts are offset away from zero by 0.5 to avoid taking the log of zero, and to reduce the variability of log-cpm for low expression genes. The library size is offset by 1 to ensure that $\left(r_{g i}+0.5\right) /\left(R_{i}+1\right)$ is strictly less than 1 has well as strictly greater than zero.

## Voom variance modelling

The above linear model is fitted, by ordinary least squares, to the $\log$-cpm values $y_{g i}$ for each gene. This yields regression coefficient estimates $\hat{\beta}_{g j}^{*}$, fitted values $\hat{\mu}_{g i}=x_{i}^{T} \hat{\beta}_{g}$ and residual standard deviations $s_{g}$.

Also computed is the average $\log -\mathrm{cpm} \bar{y}_{g}$ for each gene. The average log-cpm is converted to an average log-count value by

$$
\tilde{r}=\bar{y}_{g}+\log _{2}(\tilde{R})-\log _{2}\left(10^{6}\right)
$$

where $\tilde{R}$ is the geometric mean of the library sizes plus one.
To obtain a smooth mean-variance trend, a loess curve is fitted to square-root standard deviations $s_{g}^{1 / 2}$ as a function of mean log-counts $\bar{r}$ (Figure 2ab). Square-root standard deviations are used because they are roughly symmetrically distributed. The lowess curve [44] is statistically robust [45] and provides a trend line through the majority of the standard deviations. The lowess curve is used to define a piecewise linear function lo() by interpolating the curve between ordered values of $\bar{r}$.

Next the fitted log-cpm values $\hat{\mu}_{g i}$ are converted to fitted counts by

$$
\hat{\lambda}_{g i}=\hat{\mu}_{g i}+\log _{2}\left(R_{i}+1\right)-\log _{2}\left(10^{6}\right) .
$$

The function value $\operatorname{lo}\left(\lambda_{g a}\right)$ is then the predicted square-root standard deviation of $y_{g i}$. Finally, the voom precision weights are the inverse variances $w_{g i}=\operatorname{lo}\left(\lambda_{g i}\right)^{-4}$ (Figure 2c). The $\log$-cpm values $y_{g i}$ and associated weights $w_{g j}$ are then input into the standard limma linear modeling and empirical Bayes differential expression analysis pipeline.

Figure 2: Voom mean-variance modelling. Panel (a), gene-wise square-root residual standard deviations are plotted against average log-count. Panel (b), a functional relationship between gene-wise means and variances is given by a robust lowess fit to the points. Panel (c), the mean-variance trend enables each observation to map to a square-root standard deviation value using its fitted value for log-count.
